Final report

Approved for public release; distribution is unlimited

**ABSTRACT:** This report describes a physics-based, but relatively simple, thermal infrared computational tool that can be used in a personal computer (PC) environment to predict temperature profiles of layered media. The tool is a one-dimensional finite difference simulation code (written in FORTRAN) that is executed through a graphical user interface. Its current utility is in helping to design field tests of airborne mine detection sensor systems and to analyze the results of those tests to better understand the performance of the sensor in different environmental conditions. The tool does not address the separate issues of two- and three-dimensional effects, sensor hardware performance, sensor flight paths, or targeting algorithms.

**DISCLAIMER:** The contents of this report are not to be used for advertising, publication, or promotional purposes. Citation of trade names does not constitute an official endorsement or approval of the use of such commercial products. All product names and trademarks cited are the property of their respective owners. The findings of this report are not to be construed as an official Department of the Army position unless so designated by other authorized documents.

# Preface

---

This report was prepared as part of the U.S. Army Engineer Research and Development Center (ERDC) Countermine Phenomenology Program, which supports the U.S. Army Research, Development, and Engineering Command (RDECOM) Communications and Electronics Research, Development, and Engineering Center (CERDEC) Night Vision and Electronic Sensors Directorate (NVESD) mine detection sensor test and development programs. The NVESD Technical Monitor for this effort was Dr. Tom Broach, of the NVESD Countermine Division, located at Fort Belvoir, VA. Dr. Larry Lynch, ERDC, Geotechnical and Structures Laboratory, was the manager of the Countermine and Phenomenology Program.

Dr. John Curtis, Environmental Systems Branch (EE-C), Ecosystem Evaluation and Engineering Division (EE), Environmental Laboratory (EL), ERDC, in Vicksburg, MS, conducted this study under the direct supervision of Dr. Rose Kress, Chief of EE-C and Mr. Bruce Sabol, Acting Chief of EE-C and the general supervision of Dr. Dave Tazik, Chief of EE. Dr. Ed Theriot was Director of EL, and Dr. Beth Fleming was Acting Director of EL.

Commander and Executive Director of ERDC was COL James R. Rowan, EN. Director was Dr. James R. Houston.

# 1 Introduction

---

## Background

The U.S. Army Engineer Research and Development Center (ERDC) in Vicksburg, MS, has developed a Countermine Phenomenology Program (CPP) to support the U.S. Army Research, Development, and Engineering Command (RDECOM) Communications and Electronics Research, Development, and Engineering Center (CERDEC) Night Vision and Electronic Sensors Directorate (NVESD) mine detection sensor test and development efforts. One of the issues being addressed by the CPP is that airborne sensors that attempt to identify ground targets often suffer from unexpected high false alarm rates. ERDC researchers have demonstrated in numerous earlier studies that environmental factors often generate target-like signatures. This is true in both the thermal infrared and radar portions of the electromagnetic spectrum.

Modeling of ground target signatures has historically focused on just the targets themselves, or targets embedded in statistically noisy backgrounds. Little, if any, effort has been made to include realistic natural terrain background signatures in the design and analysis of target detection sensors and algorithms. ERDC believes that physics-based terrain element models need to be included in computational platforms that are capable of modeling the complete sensor detection process. This includes target signatures, background (natural terrain) signatures, atmospheric attenuation of those signatures, sensor hardware and flight path, and targeting algorithms.

A fundamental knowledge of the character of natural terrain and the dynamic processes that alter the properties of the terrain (predominantly season, time-of-day, and weather) are key to the success of the CPP. These models will provide a significant improvement over the current method of treating natural environments as statistical clutter. Instead, the specific geometric and material properties of the terrain can be considered and exploited by the sensor system and algorithm developers.

## Objective

The primary objective of this study is to assemble a physics-based, but relatively simple, thermal infrared computational tool that can be used in a personal computer (PC) environment to help design field tests of airborne mine detection sensor systems and to analyze the results of those tests to better understand the performance of the sensor in different environmental conditions. In particular,

this study focuses on a one-dimensional (1-D) layered media simulation code that will yield first-order understandings of target and background signatures. It does not address the separate issues of two- and three-dimensional effects, sensor hardware performance, sensor flight paths, or targeting algorithms. Those are left for a much more sophisticated computational platform that is currently being developed at ERDC.

## The TSTM/VEGIE Thermal Model

### TSTM

In 1981, two reports were published at ERDC, known then as the Waterways Experiment Station (WES), which dealt with a one-dimensional thermal model for predicting surface temperatures of natural terrain elements. The first of these, entitled “Thermal Modeling of Terrain Surface Elements” (Balick et al. 1981a), described a code named the Terrain Surface Temperature Model (TSTM), that simulated non-vegetation-covered surfaces such as bare ground or concrete slabs and their response to variable weather conditions. The basic assumption of the TSTM model was that each of the layers forming the structure, as well as the environment above the structure, was horizontally uniform. In other words, the only significant heat fluxes would be vertical. Under these conditions, physical temperatures within the structure can be found by solving the one-dimensional heat flow equation:

$$\frac{dT(z,t)}{dt} = \alpha(z) \frac{\partial^2 T(z,t)}{\partial z^2} \quad (1)$$

where  $T$  is the physical temperature of some point at a depth  $z$  below the surface at time  $t$ . The thermal diffusivity of the material at that depth  $\alpha(z)$  is defined as the ratio of the thermal conductivity of the material to the product of the mass density and specific heat of the material:

$$\alpha(z) = \frac{\kappa(z)}{\rho(z)c(z)} \quad (2)$$

Clearly, thermal diffusivity of a material measures the rate at which a change in temperature spreads through that material (Jumikis 1977).

A TSTM simulation is driven by air temperature, solar heat flux, and wind speed variations throughout the course of a day. The surface temperature is controlled by an energy balance that will be discussed in a later section.

### VEGIE

The second WES report dealt with a modification of TSTM that is described in its title: “Inclusion of a Simple Vegetation Layer in Terrain Temperature Models for Thermal Infrared (IR) Signature Prediction,” (Balick et al. 1981b). VEGIE, as the new model was named, simply added a layer of vegetative

material to the bare material through the inclusion of several new input parameters including the foliage cover fraction, an index that characterized the state of the vegetation, the graybody emissivity and solar absorptivity of the foliage, and the foliage height. The same kind of energy balance performed in TSTM is required at both the vegetation surface and the ground surface.

## Previous Applications

TSTM/VEGIE and its many variants have been used extensively in numerous ERDC applications. Early attention focused on simulations to support the ERDC mission of fixed facility camouflage, and publications include the two already referenced. Later the code was adapted to another major ERDC research effort, the Smart Weapon Operability Enhancement (SWOE) Program, and used to generate thermal IR images of targets in natural background settings (Welsh 1994).

## Code Modifications

In its original form, the TSTM/VEGIE model could be executed only on a mainframe computer. Variants of the model, used in a number of unpublished ERDC studies, were later installed on workstations and, finally, on PCs. However, none of these model variants could be called “user-friendly.” They were developed for single users and for specialized applications. One goal of this project, then, was to deliver a “user-friendly” version of the TSTM/VEGIE model that operates in a PC environment and is readily transportable from one platform to another. Data input and execution of the code were simplified through the development of a graphical user interface (GUI). Simulation results can now be readily viewed as Excel charts generated at the same time that the simulation takes place. No separate data analysis needs to be performed.

Another limitation of the original TSTM/VEGIE model was that it simulated only one diurnal cycle, utilizing an input data file that was manually created by the user. Therefore, another goal of this study was to conduct multiple-day simulations using input data files that are primarily derived from field weather station micrologger digital files. A detailed description of how to generate those files follows in a later section.

Existing TSTM/VEGIE model variants were limited to constant value thermal properties for each soil layer and constant value optical properties for the surface layer. However, thermal properties in real materials are not constant values. Among other things, they are certainly a function of moisture content (Ochsner et al. 2001). Clearly, over a period of many weeks, soil moisture conditions can change dramatically. It makes no sense to use single-valued thermal properties of soils to conduct a meaningful simulation of conditions at a test site if soil conditions change significantly during that time. Therefore, this new version of TSTM/VEGIE must allow for moisture-dependent thermal properties.

## 2 Basic Principles of the 1-D Thermal Model

---

### Model Geometry

Figure 1 is a visual representation of the TSTM model mode of operation. Although currently limited to six layers by the dimension statements of the code, theoretically any number of layers of material can be represented by a grid of nodes (equally spaced within each layer) whose spacings and properties are used to solve the finite difference form of Equation 1. The energy balance at the surface and the technique used to solve for temperatures at layer interfaces are discussed in the following sections.

### Energy Budget Terms at the Air Interface

The surface temperature of the simulated material is found at each increment of time by an energy balance that can be written in equation form as:

$$S + I - H - E - X + G = 0.0 \quad (2)$$

or

$$D - X + G = 0.0 \quad (3)$$

where

$S$  = net direct short-wave solar radiative flux density, or insolation, received at the air/solid interface

$I$  = net long-wave irradiance (energy flux density impinging on the air/solid interface) from the sky and clouds

$H$  = sensible heat exchange at the surface (primarily convective)

$E$  = latent heat exchange at the surface (primarily evaporative)

$X$  = graybody emittance (energy flux density radiating from the air/solid interface) due to the physical temperature of the surface

$G$  = energy flux density into the solid surface due to conduction

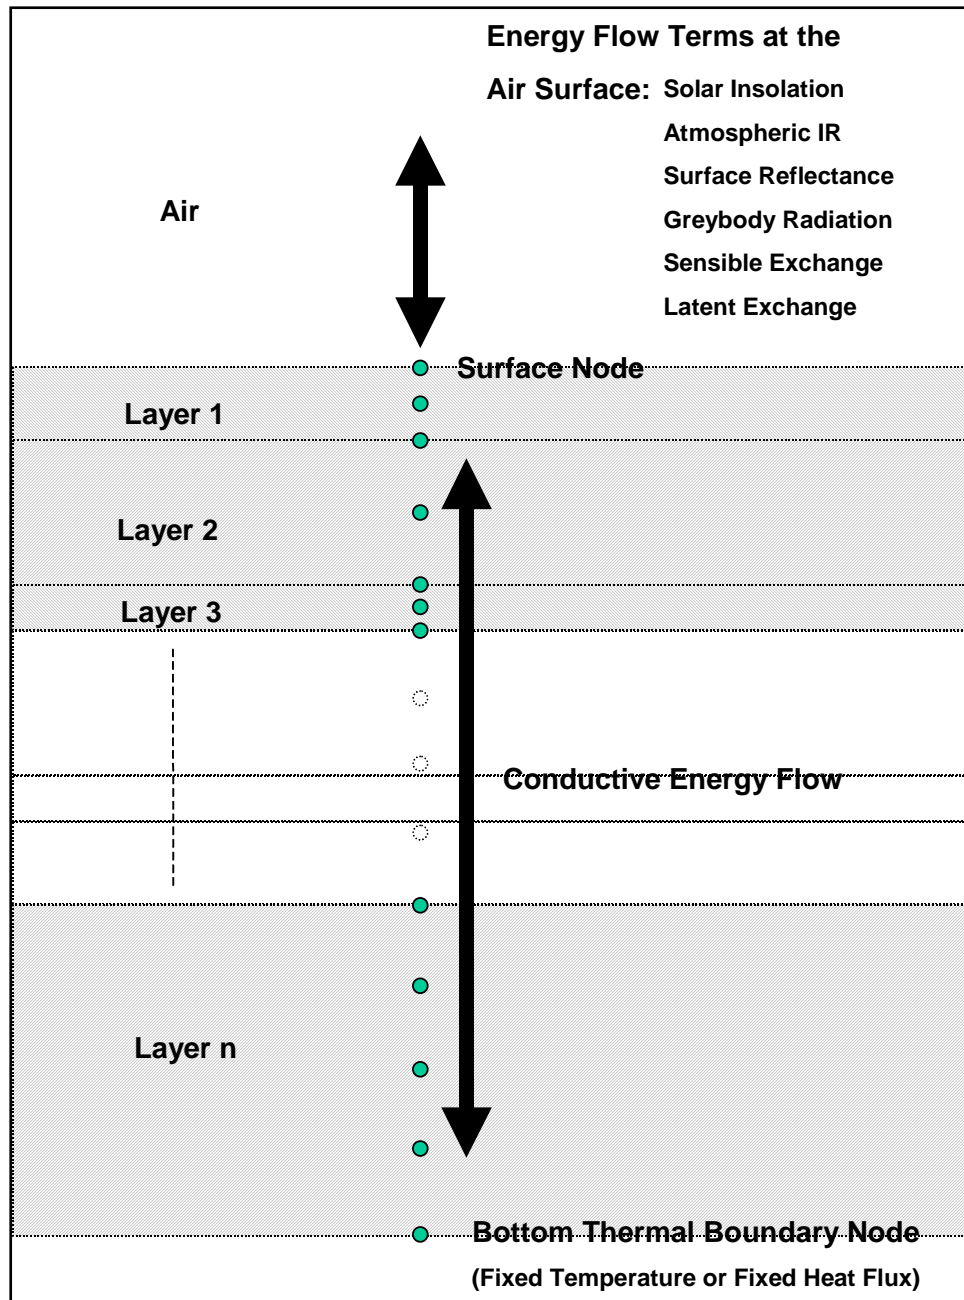

Figure 1. Geometry of the TSTM model

“Short-wave” and “long-wave” are terms used by atmospheric scientists for radiation energy in the 0.15-3.0 micron and 3.0-100 micron wavelength regions, respectively, of the electromagnetic spectrum (Oke 1987).  $I$ ,  $H$ , and  $E$  are all calculated using empirical relationships described in the original TSTM report (Balick et al. 1981a). When short-wave insolation  $S$  is not available as measured data, another empirical relationship referenced in the same report can be used to compute idealized data. This latter technique utilizes the day of the year and the latitude of the test site as controlling factors.

The graybody emittance  $X$  is calculated at each time-step within the simulation using the simple relationship:

$$X = \varepsilon_s \sigma (T_s)^4 \quad (4)$$

where

$\varepsilon_s$  = emissivity of the surface

$\sigma$  = Stephan-Boltzman constant

$T_s$  = current surface temperature predicted by the model

All that remains to define, prior to discussing the numerical solution technique used for these simulations, is the conductive energy flux density  $G$ :

$$G = k \left( \frac{\partial T}{\partial z} \right) = k \frac{(T_1 - T_s)}{\Delta z} \quad (5)$$

where

$k$  = thermal conductivity of the surface layer

$T_1$  = temperature of the first node below the surface

$\Delta z$  = spacing between the surface node and the first node below the surface

## Iterative Finite Difference Solution for Surface Temperatures

Combining Equations 3, 4, and 5, and rearranging terms, one finds that the surface temperature is the root of the following equation:

$$F(T_s) = T_s^4 + \frac{k}{\varepsilon_s \sigma \Delta z} (T_s - T_1) - \frac{D}{\varepsilon_s \sigma} = 0.0 \quad (6)$$

Newton's method is used to find that root:

$$F(T_s)_{new} = F(T_s)_{old} + \left( \frac{\partial F(T_s)}{\partial T_s} \right)_{old} dT_s \quad (7)$$

which provides an estimate for a new surface temperature (by setting  $F(T_s)_{new} = 0$ ):

$$(T_s)_{new} = (T_s)_{old} - \frac{F(T_s)_{old}}{\left(\frac{\partial F(T_s)}{\partial T_s}\right)_{old}} \quad (8)$$

The partial derivative of  $F(T_s)$  comes directly from Equation 6, in which the partial of  $D$  with respect to  $T_s$  is approximated using the previous and current estimates of the surface temperature.

## Finite Difference Solution for Energy Flow Within Layers

For material within each layer of the simulated structure, a central difference form of Equation 1 is used to calculate a new value of temperature at each node  $n$ :

$$(T_n)_{new} = (T_n)_{old} + \frac{\alpha \Delta t}{\Delta z^2} [(T_{n+1})_{old} - 2(T_n)_{old} + (T_{n-1})_{old}] \quad (9)$$

where the “ $n+1$ ” and the “ $n-1$ ” subscripts refer to the nodes immediately below and above the node of interest, respectively.

## Finite Difference Solution for Energy Flow Through Layer Interfaces

The developers of TSTM combined a truncated Taylor series for the temperature of the node adjacent to each side of an interface and the 1-D heat flow equation (Equation 1) to derive a difference expression for the partial derivative of temperature with respect to depth at that interface node looking at the interface from each of the layer materials. Each expression included an estimate for the new interface temperature. Those derivatives multiplied by the thermal conductivity of each layer resulted in two expressions for the conductive heat flux through the interface, one for each of the two adjoining materials. Assuming continuity of the heat flux through the interface, setting the two expressions equal to each other resulted in a lengthy finite difference expression for the interface temperature at the end of the time-step. Details of this derivation can be found in the original TSTM report (Balick et al. 1981a).

## Bottom Boundary Conditions

For all of the simulations conducted during this study, a fixed temperature was chosen as the bottom boundary condition. Selecting either of the other two boundary condition options (a constant heat flux or a constant heat flux combined with a constant temperature radiating surface) results in a finite difference expression that must be evaluated at each time increment. Details can be found in the original TSTM report (Balick et al. 1981a).

# 3 Executing the 1-D Thermal Code in a PC Environment

---

## Hardware and Software Requirements

TSTM/VEGIE is a Fortran code of reasonable size by today's standards. On the author's PC, the source code occupies 45 kilobytes (KB) of disk space, while the executable code occupies only 105 KB of space. In addition to the source code, a user will need a Fortran compiler to facilitate any necessary changes to the code and an Excel spreadsheet software package to execute the GUI and provide visual simulation results in chart and tabular form. The final element of the simulation tools is the input data file, which is described in detail in the next section.

Included on the CD that accompanies this report is a folder labeled "MinGW" that contains the freeware Fortran 77 compiler and other necessary files that were used by the author to conduct the simulations that follow in the next chapter. The "tstm\_files" folder contains the source code, named "tstmforgui.f" (listed in Appendix A), as well as an example input data file ("flw2004 soil.csv," listed in Appendix B) and the resulting output data file ("fort.4").

If it is necessary to make changes to the source code, the user is advised to save a copy of the original source code in a safe place before proceeding. Once that is done, the source code can be opened in any word processing window and the necessary changes made and saved. Then the code must be recompiled. That requires operating in a disk operating system (DOS) command mode. The author's Window's-based PC has a command prompt that opens a DOS window. Once there, the directory needs to be changed to that containing the source code; i.e., by entering the command:

```
cd\tstm_files
```

The source code is compiled and stored as an executable file, named "tstmforgui.exe," in the same folder by entering the command:

```
g77 tstmforgui.f -o tstmforgui
```

Simulation run times will depend upon the PC's speed and memory capabilities as well as the number of nodes simulating the structure and the number of time increments for the simulation. The author's PC has a 2.536-GHz Pentium®4 central processing unit (CPU) and 768 megabytes (MB) of random access memory (RAM). The longest simulation, for which results are shown in the next chapter, included 110 nodes to simulate a land mine over soil and utilized a time increment of 0.0008 minutes. The simulation covered 64 days of weather data and (including 3 days of iterations to achieve simulation stability, took about 24 minutes and 50 seconds of CPU time while occupying 1.7 MB of memory (determined by the size of the code and the size of the specified arrays). Using these numbers to gauge the length of other simulations, one could say that simulation run times should be on the order of 0.11 microseconds/time increment/node.

## Input Data File Creation

Appendix B contains a partial listing of an input data file used to perform one of the simulations described in the next chapter. Line numbers printed on those pages are not part of the data file; they have been added to facilitate the writing of this section.

Input data begins with a single-line description of the simulation. How it reads is the user's choice, but in most cases it will be a description of the test site being simulated. In this case, line 1 reads: "midwestern.test.site.2004." The dots between words facilitate handling of the title within the Excel spreadsheet. The number "11556" was added by a previous execution of the GUI and is not necessary for conducting a simulation.

The bulk of the input file comes from weather station data measured at the test site. Lines 2-27 on page B1 represent only a small portion of field measurement data, the first few lines and the last few lines. This particular file actually contains 11,656 lines of field data. To complete the input data file, the user needs to add a line at the end (line 28) that contains the word "End." It is used by the code to delineate the number of entries and to free the user from counting all of the lines of input data. A few columns of data have to be derived by the user. They will be described in the following paragraphs.

The entries shown on lines 29-46 of Appendix B are not needed to perform a simulation. They represent test site characterization data that has entered into the GUI prior to executing TSTM/VEGIE. These lines were then appended to the original input data file through execution of the GUI. Their only function is to populate data boxes on the GUI when a file is accessed that has been used before. This precludes the necessity of entering all of the GUI data entries by hand each time a new simulation is performed. As the listing on page B1 shows, data file entries must be comma separated (the GUI looks for a comma-separated variable (.csv) input file).

As noted above, lines 2 through 27 in Appendix B are a partial listing of the field measurement data required to execute this code. Most of these data can be

collected at a test site weather station and recorded on a field micrologger. These data will ordinarily be delivered to the user as a spreadsheet or database file (e.g., Excel). It is relatively easy to delete unnecessary columns of data and to add other columns of required data while still in the spreadsheet format.

Field measurement (and complementary) data shown in lines 2 through 27 include the following parameters for each line of data:

- Column 1 Julian day on which the following data were collected
- Column 2 Hour of the day (24-hour clock) on which the following data were collected
- Column 3 Air temperature (deg C) at a known height above the ground
- Column 4 Relative humidity (percent)
- Column 5 Barometric pressure (millibars). The -6999 entries on lines 21-27 dictate to the code that the pressure gauge failed and that a value of 1000 mbars is to be used for that point in time. Any number less than zero would trigger this event.
- Column 6 Solar insolation ( $\text{W/m}^2$ ). This is the downwelling radiation measured at the weather station by a pyranometer that typically covers the visible and near-infrared portions of the electromagnetic spectrum (400 to 1100 nanometers of wavelength). If these data are not available, the code can be directed to calculate solar insolation on a surface based on the latitude of the test site, time of year, and surface orientation.
- Column 7 Wind speed (m/s) at a known height above the ground
- Column 8 Cloud type (an integer number ranging from 1 to 8). The cloud type index identifies different cloud genera (such as cirrus, stratus, etc.) and triggers correction factors used when the simulation code is directed to generate insolation values (Balick et al. 1981a). In lieu of real data, clear sky conditions are generally identified by cloud types 1 or 2. There is a cloud correction factor for the long-wave irradiance term in the surface energy balance that is also controlled by the cloud type and the percent of cloud cover (to follow). Cloud type must be entered by hand.
- Column 9 Cloud cover (percent). This column of data is also entered by hand and could be significant if insolation is being computed. Otherwise, its effect can be negated by setting all values in this column to zero.
- Column 10 Saturation factor. This is a decimal number ranging from 0.0 to 1.0 that triggers the latent heat exchange calculation. The original documentation for the TSTM code identified this term as the relative saturation of the top surface material but used it only as a weighting factor for controlling the impact of evaporative cooling on the simulation. Furthermore, the original code used the wind speed indicator height above the ground as a factor in both the empirical latent heat exchange and sensible heat exchange functions, but the

source for those functions (Oke 1987) specified that the log height ( $z/\ln(z)$ ) of the wind speed indicator should be used in the formulation, because of an assumed exponential wind speed profile. In other words, this author had some concern about the physics behind the use of this saturation factor. As a result of this concern, log height has been inserted into the sensible and latent heat exchange relationships. Furthermore, the numbers in this data file column are now reasonable approximations to the actual near surface degree of saturation. If near-surface volumetric moisture content data are available (Column 11), then saturation factor values are computed as the ratio of that moisture content to an assumed porosity of the soil (0.40).

- Column 11 Volumetric soil moisture no. 1. Because soil thermal properties are dependent upon moisture content, an attempt was made in this code to track changes in moisture content as a function of depth in the soil. This number represents the moisture content recorded at the shallowest depth on the test site (if those data were collected).
- Column 12 Volumetric soil moisture no. 2. This is the moisture content in the soil at the deepest depth recorded on the test site. Along with a fixed moisture content boundary value at a third depth, the numbers in columns 11 and 12 were used to compute a soil moisture profile at every time step in the simulation.
- Column 13 Physical temperature no. 1. A thermistor or thermocouple temperature measurement made at the same depth in the soil. This number is not used in the simulation, but could be compared to the simulation results as a measure of goodness.
- Column 14 Physical temperature no. 2. Another temperature measurement at another depth. For the simulations reported in this study, the two temperature measurement depths in this data file corresponded to the volumetric moisture measurement depths.
- Column 15 Radiometric temperature no. 1. This column and the next contain surface temperatures measured with a staring radiometer (see the report cover photograph) that can be compared to the surface temperature predictions made by the TSTM/VEGIE code. For this study, the temperatures in column 15 are those of the land mine shown in the cover photograph.
- Column 16 Radiometric temperature no. 2. A second surface temperature that could also be used to verify the simulations. For this study, these temperatures are of the bare soil shown in the cover photograph.

Volumetric soil moisture data are not critical if soil thermal properties that are independent of moisture values are going to be used in the simulation. Physical and radiometric temperatures are also necessary only if one wishes to validate the model simulations at a given test site. With sufficient experience, a model user can generate sensible, if not accurate, results for any test site without

the burden of validating the simulations against real data. Naturally, the optimum situation is one of validated simulations.

## Model Execution Using the Graphical User Interface

Within the “tstm\_files” folder found on the enclosed CD, there exists an Excel spreadsheet called “TSTM simulation results template.xls.” It contains all of the charts that are used to display results for any simulation. To perform a TSTM/VEGIE simulation, the user must open the Excel spreadsheet on his PC, pull down the “Tools” menu, select “Macro,” then select “Macros” from the sub-menu, and then click on “TSTM” in the Macro window that appears. This action executes a Visual Basic (VBA) program that displays the GUI (Figure 2) which, in turn, controls the simulation and display of results. A listing of the TSTM macro can be found in Appendix C.

While the weather data and temperature and moisture measurements described in the previous section form the bulk of the input data file, the user must still provide other parameter values that control the flow of simulation output as well as define thermal and optical properties of the layered structure being simulated. Referring to the highlighted text and buttons shown on Figure 2, the following procedure should be followed to perform a TSTM/VEGIE simulation.

**Select Input File:** Clicking on this button produces a window that helps the user select the .csv file that contains the site description, the weather data and moistures and temperatures described above, and ends with a line containing the word “End.” If a given input data file has not been previously accessed, then additional data must be entered into the GUI input boxes by hand. If, on the other hand, the chosen data file has been previously accessed, then it is possible that the additional data have already been appended to the input data file (lines 29-46 in Appendix B). Those data will be used to automatically populate most of the GUI input data boxes as soon as the input data file is selected. In either case, the macro scans the data file for the range of days, counts the number of input data file line entries, and displays those results in the appropriate input boxes.

**Single-day simulation control:** In this area of the GUI user form, the user is allowed to choose whether he/she wants to do a single-day simulation or a simulation for all of the days listed in the input data file. For the example shown, a single-day simulation was chosen, and that day was 210. Even if a multi-day simulation was selected, the user still has the option of specifying a single day for which results will be displayed.

**Surface properties:** Several parameters are required to properly specify air-soil interface conditions. These include a solar insolation flag, optical properties, and flags that control how latent heat and sensible heat calculations will be carried out within the simulation. For this example, the flag indicating that solar insolation values would be read from the input data file was chosen. If the user had chosen to let TSTM/VEGIE calculate solar insolation values, then he/she

would have to enter the surface element slope, azimuth, and latitude of the test site into the appropriate boxes. A slope of zero degrees is horizontal. The azimuth angle of the surface, in degrees, only has meaning if the slope of the surface is not horizontal. An azimuth angle of zero degrees means that the projection of the surface normal unit vector onto the local horizontal plane at that location points south. Positive angles are clockwise from south. The test site latitude is also expressed in degrees.

**TSTM Simulation Control Panel**

Select Input File: C:\tstm\_files\flw2004 soil.csv (file name)

150 first Julian day, 214 last Julian day, 11656 number of weather parameter data entries, midwestern.test.site.2004 (file descriptor)

**single-day simulation control**

☒ single-day simulation, ☐ multi-day simulation, 210 Julian day for single-day simulation and/or for single-day charts and profiles

**surface properties**

☒ solar insolation from data file, ☐ solar insolation from calculations

0 deg slope horiz = 0, 0 deg azimuth south = 0, 0 site latitude

-0.0052 slope of emissivity function, 1 intercept of emissivity function

0.007 slope of absorptivity function, 0.4 intercept of absorptivity function

☐ fixed degree of saturation, 0 decimal value of surface degree of saturation

☒ variable degree of saturation

Figure 2. The TSTM/VEGIE Graphical User Interface

Two numbers are required in this section that represent the slope and intercept of a linear equation that defines the long-wave emissivity of the surface material as a function of surface volumetric moisture content. One method of determining the relationship between optical properties and moisture content is described in Chapter 4. If one does not know how long-wave emissivity varies as a function of moisture content, then he/she can choose emissivity to be a fixed value, in which case the slope should be set equal to 0.0.

Two additional numbers are required that represent the slope and intercept of a linear equation that defines the shortwave absorptivity of the surface material as

a function of surface volumetric moisture content. The same instructions hold for constant values as for the emissivity numbers.

The final option given to the user in the “surface properties” section is to set the flag for allowing the surface to have either a fixed degree of saturation or a variable degree of saturation. Degree of saturation is a parameter used in the calculation of latent heat transfer. The variable condition was described earlier as being related to the availability of near-surface volumetric moisture data (column 10 in the input data file). If a constant value for degree of saturation is chosen, then that value will be used for all of the simulation time-steps.

**Layer definitions:** This is the section of the GUI where the user can define up to six layers of solid material for which the simulation is being performed. In addition to the number of layers chosen, one must enter six numbers that define each layer geometry and the thermal properties of each layer. In this example, there were four material layers. The first number is the layer thickness, in centimeters. The next is the node spacing for that layer, in centimeters. They are followed by the slope and intercept of the linear relationship between thermal diffusivity (units of square centimeters per minute) and volumetric moisture content. The last two numbers are the slope and intercept of the linear relationship between thermal conductivity (units of calories per centimeter-minutes degrees Celsius) and volumetric moisture content. As with the optical properties, constant thermal properties can be defined by setting the slope values to 0.0. The “deltat” entry will be discussed below.

**Bottom boundary:** One of three conditions may be chosen for the bottom boundary of the material column being simulated. One is a constant heat flux that can be specified by the user. The second, which is the one most commonly used, is to specify a constant temperature boundary. For the example shown in Figure 2, the bottom boundary temperature was fixed at 25 °C. This is a very reasonable condition in soils over a time period of a few days, or even weeks. However, temperatures can vary at depths of 2 or 3 m when viewed on a seasonal basis. The final bottom boundary condition is that of a fixed flux lower boundary that faces a fixed-temperature radiating surface beneath the bottom boundary. One could imagine that such a condition might represent a layered medium over a cavity. The input values required for this third boundary condition include the bottom boundary flux, the temperature of the radiating surface, the emissivities of both surfaces, and two shape factors, which are related to the emitting and absorbing efficiencies of those surfaces.

**Moisture profile parameters:** Moving to the upper right area of the control panel, the user is next asked to define parameters that describe how moisture conditions in the materials vary as a function of depth. Those moisture values will be used by the code to calculate moisture-dependent thermal properties for each material layer. If the material is a man-made solid, then there will be no moisture variability, and these parameters are not needed. Furthermore, if the material is porous, but the user chooses to set thermal properties to constant values for the entire simulation, then these parameters are not needed.

If volumetric moisture data are available in the data input file (columns 11 and, possibly, 12), then the following parameters may be used to help track a

realistic moisture profile throughout the layered media. This would be a common need for simulating soils. The parameters include a depth below which the moisture content is fixed, the value of that fixed moisture content, and the depths of the volumetric moisture meters whose data are listed in columns 11 and 12 of the input data file.

**Vegetation parameters:** There are five parameters required to define surface vegetation conditions. If the first number (or only number) is zero, then the vegetation contributions will be skipped. The first parameter is a number between the values of 0.0 and 1.0 that defines the foliage cover fraction and that can be roughly related to the leaf area index. The second number is a multiplier of the stomatal resistance function for stressed plants. A third parameter is the graybody emissivity of the foliage, while the fourth number is the shortwave absorptivity of the foliage. The last parameter is the foliage height, in centimeters. A simulation using the foliage cover option was not conducted for this study. The reader is referred to the original VEGIE report (Balick et al. 1981b) for a more thorough discussion of this option.

**Miscellaneous simulation controls:** The final four parameters that can be specified by the user are found in this area of the GUI, the first of which is the interval at which the user wants to see simulation output results sent to the output file. For the simulation depicted by Figure 2, the user wanted results displayed at half-hour intervals.

The second number specifies how many iterations on the first day of simulation will be performed to achieve something of a steady-state environment. While surface temperatures are very much controlled by the energy balance at the surface, several iterations on the first day's simulation might be required to achieve a repeatable set of temperature-depth profiles for that day. Typically, only a few iterations are required to achieve stability.

Another parameter specified in this area of the GUI is the height above the ground, in centimeters, at which the wind speed measurements were made at the test site weather station. It is the number that is used in both the latent and sensible heat exchange calculations.

The final parameter is the time increment for this simulation, in minutes. Since TSTM/VEGIE functions as an explicit finite difference code, a *stability condition* exists for the time increment that must be satisfied for all material layers. Within each layer, Equation 9 controls the calculation of the next time increment. As long as the coefficient of the bracketed term is less than  $\frac{1}{2}$ , the calculation will not violate the second law of thermodynamics and the results will be stable (Holman 1968). While this is not an airtight proof, consider the following conditions. Let the temperature of the two nodes surrounding the center node in the finite difference calculation be equal and less than that of the center node. While the new temperature of the center node (at the end of the time increment) should be less than its old temperature (at the beginning of the time increment), it should not be less than that of the surrounding nodes. In mathematical notation, let

$$(T_{n-1})_{old} = (T_{n+1})_{old}$$

and

$$(T_n)_{old} = (T_{n+1})_{old} + \Delta T$$

For stability,

$$(T_n)_{new} > (T_n)_{old} - \Delta T$$

or

$$(T_n)_{new} - (T_n)_{old} > -\Delta T$$

If one defines

$$M = \frac{\alpha \Delta t}{(\Delta z)^2}$$

then from Equation 9,

$$M \left[ 2(T_{n+1})_{old} - 2\{(T_{n+1})_{old} + \Delta T\} \right] > -\Delta T$$

or,

$$M < \frac{1}{2}$$

In other words, the stability condition that must be met for each layer of material is:

$$\Delta t < \frac{(\Delta z)^2}{2\alpha} \quad (10)$$

The GUI is set up to calculate a limiting time increment for each layer according to Equation 10. If thermal diffusivity values are defined as being dependent on volumetric moisture, then a value of diffusivity at a moisture content of 40 percent is taken as an upper bound value (assumes diffusivity increases with moisture content). To display the maximum time increments allowed for each layer, the user simply presses the “Update deltats” button on the lower right corner of the GUI screen. The numbers shown in the right-hand column of the “layer definitions” area of the screen are then displayed. For the example shown

in Figure 2, the simulation time increment was controlled by the properties of the top soil layer, which required an increment of less than 0.05 minute.

**Execute TSTM:** When the user is satisfied that all simulation parameters have been properly defined, he/she may proceed with the simulation by pressing the “Execute TSTM” button at the lower-right corner of the GUI screen. What will happen immediately is that a small message window will pop up on the display screen that will say “Wait for TSTM to finish executing!” Since there is currently no way to monitor the progress of the simulation (it is proceeding through a macro shell command), the user must watch the color intensity of the message box (it will brighten when the code finishes execution) or watch the taskbar buttons across the bottom of the screen (there will be one for “tstmforgui.exe” that will disappear when the code finishes). The message box forces the macro behind the GUI to pause while the Fortran code executes. Once the simulation has finished, the user must press the “OK” button on the message box.

The next thing that will happen is another message box will appear asking: “Which column contains the measured surface temperature?” The spreadsheet page containing the simulation output values will be in the background. If the input data file contained a column of measured surface temperature data, then the charts generated by this macro can include the measured data as well as the simulated data. For the input data file described earlier, there were two columns of data containing surface measurements. Column 13 (or column “m” as seen in the background spreadsheet page) contained the mine surface measurement, and column 14 contained the soil surface measurement. If no measured surface data exists, then the user should select a column that has no data.

A second message box will then appear asking: “Which column contains the difference between measured and simulated temperatures?” Again, if such data do not exist, then the user can avoid plotting useless data by naming a column without data. For the simulation for which results will be shown in the next chapter, measured and simulated temperature difference results were displayed in column “o” for the mine surface and column “p” for the soil surface. Answering this final question and clicking the “OK” button completes the TSTM/VEGIE simulation. As the macro is currently written (Appendix C) two charts representing simulation results will be sent to the printer. One is the single-day simulation result for surface temperature compared to the measured data and the other is the set of 2-hr snapshots of temperature profiles as a function of depth for the chosen day. Example charts may be viewed in the next chapter.

## Rules of Thumb for Selecting Surface Material Properties

This model can be executed in one of two ways. First of all, one can select material properties for all of the layers of material based on published data and previous experience with the model and simply predict surface temperatures for whatever the input weather parameters may be.

The second method (which is much more realistic for natural materials with thermal properties that are expected to vary with volumetric moisture content) is to select weather extremes for which iterative single-day simulations will be performed to establish the optimum set of properties for each set of weather

conditions. For example, one can choose a day for which site soils would be quite dry near the surface. While allowing the code to use moisture-depth profiles specified by the user (see previous section), the user can determine the optimum values of constant thermal and optical properties that give the best comparison to measured data. Those values can then be assigned to an average soil moisture for that day. The user can then select a wet-soil day and repeat the process. Finally an intermediate soil moisture day can be simulated in the same trial and error manner. The user then will have a crude relationship between each property and soil moisture which, in turn, becomes part of the input data file for a complete multiple-day simulation for that test site. An example of this process is shown in the next chapter.

The following table provides a useful summary of how property value changes for these iterative simulations will change the resulting predicted daytime temperatures of the surface. While the effects of long-wave emissivity and short-wave absorptivity are very sensible, the impact of changes in thermal diffusivity and thermal conductivity are less intuitive. One way to rationalize their effects is to combine the defining relationships for specific heat and thermal diffusivity in the following way. Consider first the relationship that defines how much heat energy  $Q$  is required to raise the temperature of a lump of material (mass  $m$  and volume  $V$ ) by an amount labeled  $\Delta T$  (Ohanian 1985):

$$Q = mc\Delta T = \rho V c \Delta T \quad (11)$$

When combined with Equation 2, which defines thermal diffusivity, one can easily show that

$$\Delta T = \frac{\alpha Q}{\kappa V} \quad (12)$$

In other words, for a given amount of heat energy flowing into a fixed volume of material, an increase in thermal diffusivity will result in an increase in material temperature. The inverse is true for an increase in thermal conductivity.

<b>Table 1</b> <b>Rules of Thumb for Selecting Surface Material Properties</b>		
<b>Material Property</b>	<b>Physical Description</b>	<b>Effect on Predicted Daytime Temperatures Due to an Increase in the Property Value</b>
Long-wave Emissivity	A measure of the rate at which a surface can radiate IR energy to its surroundings	Decrease
Short-wave Absorptivity	The fraction of incoming solar radiation that is absorbed by the surface material	Increase
Thermal Diffusivity	The ratio of thermal conductivity to volumetric heat capacity. A measure of the speed with which temperature spreads throughout the material.	Increase
Thermal Conductivity	A measure of the rate of heat energy flow through the material to a lower temperature reservoir.	Decrease

## 4 Example Simulations

---

Weather data, volumetric soil moisture values, and radiometric surface temperature measurements were collected at a midwestern test site during the summer of 2004. These data covered a time period of 64 days at a rate of one set of readings every hour for the first 56 days and one set of readings every minute for the next 8 days.

### Determining Moisture-Dependent Soil Properties

Laboratory data clearly show that soil thermal properties are a strong function of moisture content (Ochsner et al. 2001), with a general trend of increasing thermal conductivity, volumetric heat capacity, and thermal diffusivity with increasing volumetric moisture content. Those same measurements also show that the spread in the data is large enough that simple model fits cannot be used for predictive purposes. In fact, other sources argue that thermal diffusivity decreases with increasing moisture content at higher moisture values, because the volumetric heat capacity increases faster than the thermal conductivity (Jumikis 1977).

If a realistic simulation of a layered test site soil is going to be performed over a period of several weeks, during which multiple rain events followed by drying periods occur, then some accounting for a change in thermal (and possibly optical) properties with changing soil moisture content must be made. The approach taken by the author to deal with this dilemma is to conduct at least three single-day simulations for different soil moisture conditions and adjust the surface material properties to best match measured data. Simple model fits to those thermal (and optical) properties plotted against soil moisture content can then be used to define the input data file properties for a multi-week simulation in which the soil moisture conditions were highly variable.

For the following simulations of surface temperatures at a midwestern U.S. test site, single-day calculations were done for day 193 (average measured volumetric moisture content equal to 5.5 percent, peak measured surface temperature equal to 54 deg C), day 178 (7.0 percent, 44 deg C), and day 212 (15.0 percent, 28 deg C). Trial-and-error simulations were performed for each of these days, resulting in a different set of values for both the thermal properties and the optical properties of the surface soil. Those values and the corresponding regression model fits are shown on Figure 3.

It is important to remember that these relationships between thermal and optical properties and volumetric soil moisture content hold for this site and this type of soil. At another test site, or even at another location within this particular test site, a similar single-day simulation exercise might result in a much different set of thermal and optical parameters. In other words, *thermal and optical properties for soils are very likely to be site-dependent.*

Figure 3. Test site thermal and optical properties of soil as a function of volumetric moisture content

## A Simulation of Soil Surface Temperatures

One goal of this study is to demonstrate that the modified TSTM/VEGIE code can do a reasonably good job of predicting surface temperatures under a variety of weather conditions. Weather data, surface temperature data, and soil moisture data collected at a midwestern U.S. test site during the summer of 2004 were used as input and validation data for two 64-day simulations of a bare soil surface and a metallic land mine surface. In a later section, these simulation results will be used to calculate a predicted thermal contrast between the mine surface and the soil surface.

All of the following charts are self-explanatory, but some commentary may be useful in interpreting the results. Simulation results for any single day could have been chosen for display. In this case, day 193 (one of the hotter, drier days) was chosen, and those results are shown in Figures 4 and 5. Obviously, one can never expect perfect simulation results; however, predicted surface temperatures compare very well with measured data for this day. Predicted results appear to lag the daytime data in a manner that results in predicted morning temperatures that are as much as 4 °C lower than measured data and early evening temperatures that are as much as 5 °C higher than the measured values. The material properties could have been adjusted for this one day to give much smaller differences between predictions and measurements, but that would violate the spirit of this exercise, which was to demonstrate physically sound simulations over a variety of weather conditions using one set of material property definitions.

Figure 6 compares the predicted surface temperature with the measured values for all 64 days of the simulation. In general, the results are quite reasonable, except for extremely wet and overcast conditions. One of the model input parameters that was not measured and used properly was that of percent cloud cover. Those data would have had an impact on simulation results through the long-wave irradiance term in the surface energy budget equation (Equation 2). In addition, there is still some question as to whether or not the latent heat exchange and sensible heat exchange formulations are being used properly. That question remains to be answered through future research.

Figure 7 summarizes the differences between the predicted surface temperatures and the measured data. Although the results appear somewhat noisy, note that the average difference is only 1.1 °C and that the standard deviation of the differences over the entire 64-day period is only 3.7 °C.

The final results shown (Figure 8) for this simulation are the soil temperature profiles for the even hours of day 193. Note that, even though three different layers of soil with the same thermal properties but different node spacings were used for this simulation, the resulting soil temperature profiles are very smooth and clearly show physically correct results such as the thermal inertia of the underlying soil (there is a time lag for temperature change beneath the surface). It would also appear that the assumption of a fixed bottom boundary temperature of 25 °C is not unreasonable, although in hindsight, a fixed temperature of 30 °C, or so,

might have been a better choice. Further note that the zone of active temperature fluctuations is limited to a depth of about 40 cm.

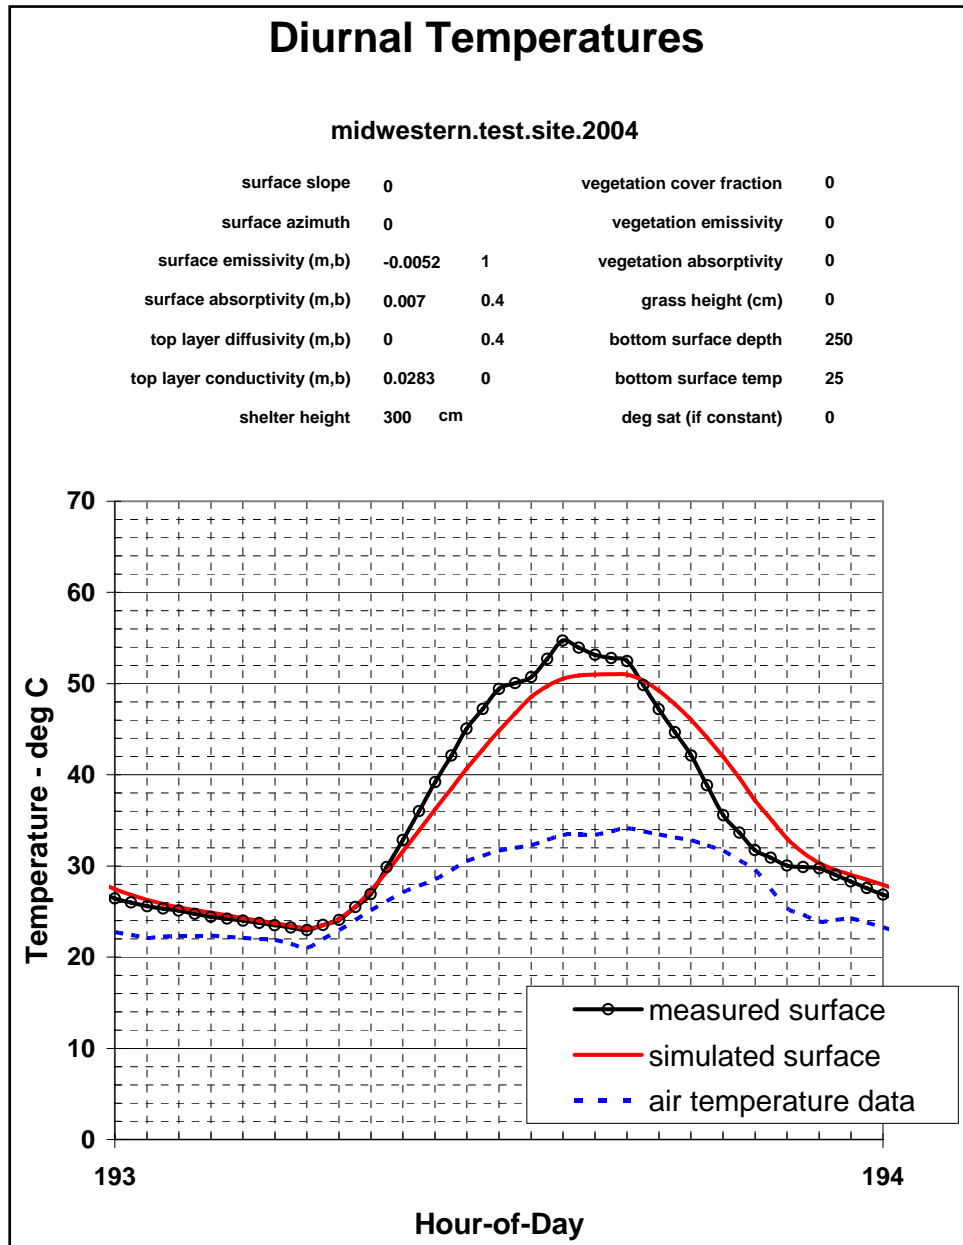

Figure 4. Predicted and measured soil temperatures for the midwestern U.S. test site (day 193)

## A Simulation of Land Mine Surface Temperatures

A second 64-day simulation was performed for a metallic landmine sitting on soil at this test site (see report cover photograph). The geometry of this mine was approximated by a three-layer structure consisting of a 0.33-cm-thick carbon steel jacket filled with dense concrete. The overall thickness was taken to be

about 10 cm. The latent heat exchange term in Equation 2 was turned off for this simulation by setting the saturation factor value at zero for all time-steps. Under those conditions, thermal and optical properties for the painted steel and thermal properties for the concrete were chosen to best predict the measured surface temperatures for days 193 and 212 (extremes in weather conditions). Results are shown in the following charts.

Figure 5. Predicted and measured energy fluxes for the midwestern U.S. test site soil simulation (day 193)

It appears that the land mine simulation was about as good as the soil simulation, with an average difference of -1.1 °C and a standard deviation of 4.9 °C. The most noteworthy result is that of the temperature profiles shown in Figure 13. The profiles within the underlying soil (below 10 cm) have a much different character than those generated for the soil simulation (Figure 8). The

temperature of the soil in contact with the mine is forced to track the temperature of the bottom of the mine. The thermal inertia displayed in Figure 8 is not as evident on this chart. What the bottom boundary temperature should be is certainly left to speculation, and the zone of influence extends a little farther into the underlying soil.

## Landmine-Soil Thermal Contrasts

Of paramount importance to the airborne sensor community is the temperature contrast between man-made targets, such as the land mine, and background materials, such as the soil. Thermal infrared sensors that image the apparent temperatures of objects within their fields of view can easily detect large differences between targets and backgrounds. During the daylight hours, those contrasts can be large and positive (the target is hotter than the background). On the other hand, man-made materials can be cooler than their natural surroundings at night, resulting in a negative thermal contrast between the two.

Figure 13 shows both the predicted and measured thermal contrasts between the land mine and the surrounding soil for only 2 days during the 64-day simulation. In both cases, the positive contrasts are much greater than the negative contrasts, although the simulations produce greater extremes. What is most interesting occurs at the “cross-over times.” Those are the times of day when the contrast polarity switches from positive to negative, or vice-versa. While most IR sensors have the ability to detect fairly small differences in temperature between two objects, such differences can easily be washed out in the array of contrasts at points surrounding the target. Therefore, one wants to avoid using such a sensor to search for targets at times near the cross-overs. For days 193 and 194, the morning cross-over occurs between 8:00 AM and 9:00 AM, while the evening crossovers take place between 8:00 PM and 9:00 PM. For another season of the year, these cross-over times will probably occur at different times. It is noteworthy that the predicted cross-over times take place within an hour of the measured results.

# 5 Summary and Recommendations

---

## Summary

An existing 1-D finite difference surface temperature prediction model was modified to perform multiple-day simulations of natural terrain and man-made surfaces using weather station data as the primary input. The original code was modified in a number of ways, including the ability to exercise the code on a PC, to input thermal and optical material properties that vary with moisture content, and to utilize more realistic latent and sensible heat exchange models. An Excel spreadsheet was developed to help display simulation results in meaningful ways.

The modified code was exercised against 64 days of weather, soil moisture, and surface temperature data collected at a midwestern U.S. test site. Comparisons of measured data with predicted results for bare soil and a metallic land mine were quite favorable. Of particular interest were the daily displays of thermal contrast between the land mine and the bare soil. While the predicted magnitudes of peak thermal contrasts exceeded the measured values, crossover times (times of day when the thermal contrast goes to zero) for both the real data and the simulations were within an hour of each other.

It is anticipated that this code can make reasonable, physics-based predictions for man-made target surface temperatures as well as those of background materials for any test site in the world. Such simulations can be used to anticipate times of day during which airborne sensors can be expected to have difficulty in detecting targets against natural backgrounds. As this code only computes physical temperatures of the surfaces, it cannot be expected to predict sensor performance. That would be a function of the sensitivity of the sensor detectors, the angular resolution of the sensor, and the algorithms that might be used to process measured data.

Furthermore, it must also be recognized that this code cannot simulate two- and three-dimensional effects, which certainly must play a significant part in determining the temperature distribution around a finite three-dimensional target in a large heterogeneous background. Such studies will require a computational test bed that operates on a much larger computer system than the author's PC.

## Recommendations

Several improvements could be made to the code and analysis procedures that would create a more user-friendly environment in which to perform simulations. For example, as the original authors of the TSTM/VEGIE simulation code suggested, one could make the code be implicit in nature, in which the temperatures on the right side of Equation 9 would be written in terms of values at the end of the time-step. The resulting iterative solution would ensure time-step stability.

Another improvement would be to develop an optimization routine for determining material properties. The current process for finding an optimum set of surface material thermal and optical properties is best performed by varying each of the four property values in question (long-wave emissivity, short-wave absorptivity, thermal diffusivity, and thermal conductivity) one at a time and comparing the predicted surface temperatures to measured values. It requires a lot of analyst judgment and the use of the rules of thumb shown in Table 1 in the text. It should be possible to automate that search for an optimum set of values, perhaps using the standard deviation of the difference between the predicted temperatures and measured temperatures as an optimization metric.

14 C   MAJOR REVISIONS IN SEPT-DEC 2004 BY JOHN CURTIS
15 C   REVISIONS INCLUDE MET STATION WEATHER FILES AS INPUT FOR
16 C   MULTIPLE-DAY SIMULATIONS AS WELL AS UTILIZING MOISTURE-
17 C   DEPENDENT SOIL THERMAL PROPERTIES AND OPTICAL PROPERTIES
18 C
19 C   MORE REVISIONS IN JUNE 2005 TO MAKE INPUT COMPATIBLE WITH
20 C   A GRAPHICAL USER INTERFACE DEVELOPED BY CURTIS

REPORT DOCUMENTATION PAGE				Form Approved OMB No. 0704-0188	
Public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing this collection of information. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing this burden to Department of Defense, Washington Headquarters Services, Directorate for Information Operations and Reports (0704-0188), 1215 Jefferson Davis Highway, Suite 1204, Arlington, VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to any penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number. <b>PLEASE DO NOT RETURN YOUR FORM TO THE ABOVE ADDRESS.</b>

13. SUPPLEMENTARY NOTES					
14. ABSTRACT  This report describes a physics-based, but relatively simple, thermal infrared computational tool that can be used in a personal computer (PC) environment to predict temperature profiles of layered media. The tool is a one-dimensional finite difference simulation code (written in FORTRAN) that is executed through a graphical user interface. Its current utility is in helping to design field tests of airborne mine detection sensor systems and to analyze the results of those tests to better understand the performance of the sensor in different environmental conditions. The tool does not address the separate issues of two- and three-dimensional effects, sensor hardware performance, sensor flight paths, or targeting algorithms.
